(Dated: June 8, 2015)

Lattice gauge theory has provided a crucial non-perturbative method in studying canonical models in high-energy physics such as quantum chromodynamics. Among other models of lattice gauge theory, the lattice gauge-Higgs model is a quite important one because it describes wide variety of phenomena/models related to the Anderson-Higgs mechanism such as superconductivity, the standard model of particle physics, and inflation process of the early universe. In this paper, we first show that atomic description of the lattice gauge model allows us to explore real time dynamics of the gauge variables by using the Gross-Pitaevskii equations. Numerical simulations of the time development of an electric flux reveal some interesting characteristics of dynamical aspect of the model and determine its phase diagram. Next, to realize a quantum simulator of the U(1) lattice gauge-Higgs model on an optical lattice filled by cold atoms, we propose two feasible methods: (i) Wannier states in the excited bands and (ii) dipolar atoms in a multilayer optical lattice. We pay attentions to respect the constraint of Gauss's law and avoid nonlocal gauge interactions.

I. INTRODUCTION

Cold atoms in an optical lattice have been used as versatile quantum simulators for various many-body quantum systems and some important results were obtained [1]. Recently, there appeared several proposals to simulate models of lattice gauge theory (LGT) [2–4]. Since its introduction, LGT has been an indispensable tool to studying the non-perturbative aspect of quantum models in the high-energy physics (HEP) such as confinement of quarks, the spontaneous chiral-symmetry breaking, etc. Atomic simulations, if realized, shall certainly clarify the dynamics, i.e., the time evolution of lattice gauge models, which is far beyond the present theoretical standard.

At present, the proposals are classified into two approaches. In the first approach [5–11], atoms with spin degrees of freedom are put on links of the optical lattice. Such a lattice gauge model is called the “quantum link model” or “gauge magnet” [12–14]. Although the Gauss's law (divergence of the electric field is just the charge density of matter fields) [15] is assured as the conservation of “angular momentum” [16], the Hilbert space of this model itself truncates the full Hilbert space of the original U(1) LGT studied in HEP.

In the second approach [17], one considers the Bose-Einstein condensate (BEC) of atoms put on each link of the two or three dimensional optical lattice. The U(1) phase variable of the complex amplitude of BEC plays a role of dynamical gauge field on the links, and its density fluctuation corresponds to the electric field, the conjugate variable of the gauge field [17, 18]. Adopting the phase variable of the atomic field as the gauge field assures us that we deal with a U(1) field as in HEP in contrast with the first approach. However, to keep the Gauss's law and the short-range gauge interactions simultaneously, a complex design of the system and also a fine tuning of interaction parameters are generally needed in the exper-

imental setups [17, 18].

Recently, we proposed a perspective to overcome the difficulty to respect the local gauge invariance in the second approach [19]. Namely, the cold atomic simulator of the LGT *without* exact local gauge invariance due to untuned interaction parameters (the Gauss's law is not satisfied) can be a simulator for a lattice “gauge-Higgs” (GH) model [20] *with* exact local gauge invariance, where the unwelcome interactions that violate the Gauss's law are viewed as gauge-invariant couplings of the gauge field to a Higgs field.

Needless to say, the GH model is a canonical model of Anderson-Higgs mechanism and plays a very important role in various fields of modern physics. Its list includes mass generation in the standard model of HEP, phase transition and the vortex dynamics [21] in superconductivity, time-evolution of the early universe such as the dynamics of Higgs phase transition and the related problems of topological defects, uniformity, etc. [22, 23]. Atomic quantum simulation of this model is certainly welcome because it simulates the real time evolution of the above exciting phenomena.

In what follows, we consider the second approach to discuss the atomic quantum simulator of the U(1) lattice GH model by using cold atoms in a two-dimensional (2D) optical lattice. Our target GH model has a nontrivial phase structure, i.e., existence of the phase boundary between confinement and Higgs phases, and this phase boundary is to be observed by cold-atom experiments. In the experiments, each phase could be generally studied through the non-equilibrium dynamics of the system, which are detected by e.g., the density distribution of the time-of-flight imaging after the system is perturbed. As a reference to such experiments, we make numerical simulations of the time-dependent Gross-Pitaevskii (GP) equation and observe the real-time dynamics of the atomic simulators. In particular, we study the dy-

namical stability of a single electric flux connecting two charges with opposite signs, corresponding to a density hump and dip for the atomic simulators. We stress that this dynamical simulation in an interacting atomic system gives a new theoretical tool for the analysis of lattice gauge models far beyond the present standards of the theoretical study on the LGT using the “classical” Monte-Carlo simulations, the strong-coupling expansion, etc. The obtained phase boundary is discussed and compared with that of the Monte-Carlo simulations. Next, we propose two realistic experimental setup for the quantum simulators. To respect the constraint of Gauss’s law and avoid nonlocal gauge interactions, it is necessary to tune suitably the intersite density-density interaction of the hamiltonian. We give two ideas: (i) Using Wannier states in the excited bands and (ii) Using dipolar atoms in a multilayer optical lattice, both of which are reachable under current experimental techniques.

The paper is organized as follows. In Sec.II, we introduce our target hamiltonian of the U(1) lattice GH model starting from the extended Bose-Hubbard (BH) model with the intersite density-density interaction. The exact correspondence of the atomic system to the LGT has been discussed in Ref. [19]. In Sec. III, we present the results of the dynamical simulations by means of the GP equation, which is obtained under the saddle-point approximation of the real-time path integral of the two quantum hamiltonians, i.e., the original BH model and the target GH model. The obtained dynamical phase diagram is compared with the result of the Monte-Carlo simulations. We give two proposals for experiments to construct realistic atomic simulators for the lattice GH model in Sec. IV. Method A in Sec. IV A relies on extended orbits of the Wannier functions in excited bands of an optical lattice. Another method B utilize the long-range interaction between atoms in different layers of 2D optical lattices. Both methods may be possible to tune the intersite density-density interactions in the 2D BH system for our purpose. Section V is devoted to our conclusion and an outlook on future direction.

II. FROM BOSE-HUBBARD MODEL TO THE GAUGE-HIGGS MODEL

Corresponding to the simplest realistic experimental situation of the quantum simulator, we focus on the boson system defined on a 2D square lattice. We start from a generalized BH hamiltonian [1]

$$\hat{H} = - \sum_{k,a \neq b} J_{ab} \hat{\psi}_a^\dagger \hat{\psi}_b + \frac{V_0}{4} \sum_{k,a} \hat{\rho}_a (\hat{\rho}_a - 1) + \sum_{k,a \neq b} \frac{V_{ab}}{2} \hat{\rho}_a \hat{\rho}_b, \quad (1)$$

which describes the bosons in a single band of a 2D optical lattice. The bosonic atomic fields $\hat{\psi}_a = \exp(i\hat{\theta}_a) \sqrt{\hat{\rho}_a}$ are put on the site a of the square optical lattice. The summation is taken over the unit cell k (yellow region in

FIG. 1. Relation between two 2D lattices. The dashed red lines indicate the 2D optical lattice with the square geometry, and cold atoms reside on its sites denoted by black crosses. Its unit cell consists of a pair of white and blue squares (yellow region). The filled black lines indicate the 2D gauge lattice on which the U(1) lattice GH model is defined. Then the cold atoms are viewed to sit on each link of the gauge lattice to play the role of gauge field. The relevant sites of the original lattice (links among the site r of the gauge lattice) in Table I are numbered as $a = 1 \sim 6$, as $a = 1 = (r, 1)$, $2 = (r - 2, 2)$, $3 = (r - 1, 1)$, $4 = (r, 2)$, $5 = (r + 2, 1)$, $6 = (r + 1, 2)$, where (r, i) represents the link of the gauge lattice emanating from the site r into the positive i ($= 1, 2$)-th direction. The gauge lattice plays an important role also in the study of the BH model with $V_{ab} = 0$ in a different context [24].

Fig. 1) and, in each unit cell, over the the site $a(b) \in 1-6$. We confine ourselves to the nearest-neighbor (NN) and next-nearest-neighbor (NNN) couplings for the site pairs (a, b) in the 1st and 3rd terms. The parameters $J_{ab}(= J_{ba})$, V_0 , and $V_{ab}(= V_{ba})$ are the coefficients of the hopping, the on-site interaction, and the intersite interaction, respectively, and calculable by using the Wannier functions in a certain band. The intersite terms V_{ab} may arise when the atoms have a long-range dipole-dipole interaction (DDI) [25], or when the atoms are populated in the excited bands of the optical lattice [26].

To map the BH model onto the hamiltonian of LGT, we consider the diagonal lattice whose sites $r = (r_1, r_2)$ are positioned on the centers of the colored squares in Fig. 1. Then, the original sites can be viewed as links of the diagonal lattice. The links are labeled as (r, i) with the direction index $i = 1, 2$. To derive the hamiltonian of the target GH model, we consider the case such that J_{ab} and V_{ab} take values according to the following three groups (i)-(iii) for pairs (a, b) of sites as shown in Table I

[17, 19]. We note that Table I breaks the translational symmetry of atomic interactions, e.g., $V_{24} \neq 0$ while $V_{15} = 0$. Next, we assume that the equilibrium atomic density is uniform and sufficiently large $\rho_0 \equiv \langle \hat{\rho}_{r,a} \rangle \gg 1$. Then, we expand the density operator as $\hat{\rho}_{r,i} = \rho_0 + \hat{\eta}_{r,i}$, and keep terms up to $O(\hat{\eta}^2)$ to obtain

$$\begin{aligned} \hat{H} \simeq & \frac{1}{2\gamma^2} \sum_r \left[\sum_i (\hat{\eta}_{r,i} + \hat{\eta}_{r-i,i}) \right]^2 + \frac{V'_0}{2} \sum_{r,i} \hat{\eta}_{r,i}^2 \\ & - \rho_0 J \sum_{r,i,\delta} \cos(\hat{\theta}_{r,i} - \hat{\theta}_{r,\delta}) - 2\rho_0 J' \sum_{r,i} \cos(\hat{\theta}_{r,i} - \hat{\theta}_{r-i,i}) \\ & - 2\rho_0 J'' \sum_{r,i} \cos(\hat{\theta}_{r,i} - \hat{\theta}_{r-i,i}), \end{aligned} \quad (2)$$

where $V'_0 \equiv V_0 - 2\gamma^{-2} > 0$, (r, δ) represents the NN links of (r, i) , and $\bar{1} \equiv 2$, $\bar{2} \equiv 1$. The first order term $O(\hat{\eta})$ is absent due to the stability condition for $\rho_0 = [\mu + 4J + 2(J' + J'')]/(V'_0 + 8\gamma^{-2})$ with the chemical potential μ . In the atomic simulators of LGT, the phase $\hat{\theta}_{r,i}$ plays a role of a gauge variable on the link (r, i) and its conjugate momentum $\hat{\eta}_{r,i}$ is the electric field $-\hat{E}_{r,i}$ [17–19]. By replacing $\hat{\eta}_{r,i} \rightarrow (-)^r \hat{\eta}_{r,i}$ and $\hat{\theta}_{r,i} \rightarrow (-)^r \hat{\theta}_{r,i}$ with $(-)^r \equiv (-)^{r_1+r_2}$, the first term in the rhs of Eq. (2) describes the “Gauss’s law” as $(2\gamma^2)^{-1} \sum_r [\sum_i (\hat{\eta}_{r,i} - \hat{\eta}_{r-i,i})]^2 \simeq (2\gamma^2)^{-1} \sum_r (\nabla \cdot \mathbf{E})^2$. The two conditions $V_{(i)} = V_{(ii)} (= \gamma^{-2})$ and $V_{(iii)} = 0$ in Table I are necessary to generate the $(\nabla \cdot \mathbf{E})^2$ term without nonlocal interaction among $E_{r,i}$. If these conditions are not fulfilled, a product $\hat{E}_{r,i} \hat{E}_{r',i'}$ over the different links appears additionally, and it gives rise to long-range interactions among the gauge field $\theta_{r,i}$ in the target GH model. Although such a model still respects gauge symmetry, we reject it here because all LGTs relevant to HEP are generally models with local-interaction.

In Ref. [19], it was shown that the partition function $Z = \text{Tr} \exp(-\beta \hat{H})$ of the atomic model of Eq. (2) is equivalent to that of the GH model. The GH model is the U(1) lattice gauge model on the (2+1)D lattice, and its parti-

tion function is given by

$$\begin{aligned} Z_{\text{GH}} = & \int [dU][d\phi] \exp(A_I + A_P + A_L + A_{2I} + A_{I^2}), \\ A_I = & \frac{1}{2} \sum_{x,\mu} c_{1\mu} (\bar{\phi}_{x+\mu} U_{x,\mu} \phi_x + \text{c.c.}), \\ A_P = & \frac{1}{2} \sum_{x,\mu < \nu} c_{2\mu\nu} (\bar{U}_{x,\nu} \bar{U}_{x+\nu,\mu} U_{x+\mu,\nu} U_{x,\mu} + \text{c.c.}), \\ A_L = & \frac{c_3}{2} \sum_x \left[\bar{\phi}_{x+1+2} U_{x+1,2} U_{x,1} \phi_x \right. \\ & + \bar{\phi}_{x+2} \bar{U}_{x+2,1} U_{x+1,2} \phi_{x+1} + \bar{\phi}_x \bar{U}_{x,2} \bar{U}_{x+2,1} \phi_{x+1+2} \\ & \left. + \bar{\phi}_{x+1} U_{x,1} \bar{U}_{x,2} \phi_{x+2} + \text{c.c.} \right], \\ A_{2I} = & \frac{c_4}{2} \sum_x \sum_{i=1,2} \left[\bar{\phi}_{x+i} U_{x,i} U_{x-i,i} \phi_{x-i} + \text{c.c.} \right], \\ A_{I^2} = & \frac{c_5}{2} \sum_x \left[\bar{\phi}_{x+2+1} U_{x+2,1} \phi_{x+2} \cdot \bar{\phi}_{x+1} U_{x,1} \phi_x \right. \\ & \left. + (1 \leftrightarrow 2) + \text{c.c.} \right]. \end{aligned} \quad (3)$$

Here, $x = (x_0, r_1, r_2)$ is the site index of the (2+1)D lattice with the discrete imaginary time $\tau = x_0 \times \Delta\tau$ [$x_0 = 0, \dots, N_0$, $N_0 \Delta\tau = \beta \equiv (k_B T)^{-1}$] and the 2D spatial coordinate r_1, r_2 . μ and ν ($= 0, 1, 2$) are direction indices. The U(1) gauge variables $U_{x,\mu} \equiv \exp(i\theta_{x,\mu})$ are defined on the link (x, μ) . $\theta_{x,\mu}$ ($\mu = 1, 2$) corresponds to the eigenvalue of the phase of atomic operator $\hat{\psi}_{r,a}$ through $\theta_{x,\mu} = \hat{\theta}_{r,i}$. The complex field ϕ_x defined on site x is a bosonic matter field, referred to “Higgs field” in the London limit, taking the form $\phi_x = \exp(i\varphi_x)$ with frozen radial fluctuations. The integration $\int [dU][d\phi]$ is over the angles $\theta_{x,\mu}, \varphi_x \in [0, 2\pi)$. The coefficients $c_1 \sim c_5$ are real dimensionless parameters for interactions among gauge fields. Each term of the action, hence the action itself, and the integration measure are invariant under the local U(1) gauge transformation, $\theta_{x,\mu} \rightarrow \theta_{x,\mu} + \lambda_{x+\mu} - \lambda_x$, $\varphi_x \rightarrow \varphi_x + \lambda_x$.

According to Ref. [19], the atomic simulator of the GH model in a 2D system corresponds to the following case of parameters for $c_{1\mu}, c_{2\mu\nu}$:

$$\begin{aligned} c_{10} = c_1, \quad c_{11} = c_{12} = 0, \\ c_{201} = c_{202} = c_2, \quad c_{212} = 0. \end{aligned} \quad (4)$$

In terms of the atomic system, the c_1 - and c_2 -terms describe the sum of the self coupling and the neighboring correlations of densities of atoms, and the c_3 - and $c_{4,5}$ -terms describe the NN and the NNN hopping terms respectively. The relations among the parameters of Eq. (2) and Eq. (3) are

$$\begin{aligned} c_1 = \frac{\gamma^2}{\Delta\tau}, \quad c_2 = \frac{1}{\Delta\tau V_0}, \quad c_3 = 2J\rho_0\Delta\tau, \\ c_4 = 2J'\rho_0\Delta\tau, \quad c_5 = 2J''\rho_0\Delta\tau, \end{aligned} \quad (5)$$

In experiments, we expect low T ($\lesssim 10$ nK set by the parameters of \hat{H}), and the quantum phase transitions may

TABLE I. Atomic parameters J_{ab} and V_{ab} in Eq. (1). Those not shown below are set to zero to avoid double counting [(1, 6), etc.] or due to longer-ranges [(3, 5), etc].

group	range	(a, b)	J_{ab}	V_{ab}

be explored in a multi-dimensional space parametrized by the dimensionless and $\Delta\tau$ -independent combinations such as $c_1/c_2 = \gamma^2 V'_0$, $c_3 c_2 = 2J\rho_0/V'_0$, etc.

III. REAL-TIME DYNAMICS OF SIMULATORS: STABILITY OF AN ELECTRIC FLUX

In actual experiments observing the nonequilibrium time-evolution of a quantum simulator, the results globally reflect the phase structure of the target model. The (2+1)D GH model supports the confinement phase and the Higgs phase (see Appendix A). The confinement phase is characterized by the strong phase fluctuation; when static two point charges, such as density defects created by the focused potentials, are put on, they are connected by an almost straight electric flux (linearly-rising confinement potential). In contrast, the Higgs phase possesses the phase coherence over the system and the system can be regarded as a superfluid phase; the density wave can propagate around the charges [19].

To get some insight on the time-evolution of the system, we study the dynamical features of the simulators through numerical simulations under the mean-field approximation of the two quantum hamiltonians: the base BH model Eq. (1) and the target GH model Eq. (2). The time-dependent equations can be derived from the real-time path-integral formulation under the saddle-point approximation (we put $\hbar = 1$). The operators of the original hamiltonian are replaced by the c -number fields. We confine ourselves to the models with only NN hopping $J \neq 0$ and $J' = J'' = 0$ for simplicity. We note in advance that the mean-field equations necessarily underestimate quantum fluctuations, and their results should be taken as a guide to practical and future experiments which are expected to reveal the real dynamics of quantum systems.

The equation of motion for ψ in the BH model of Eq. (1) can be derived from the Lagrangian $L = -\sum_r \sum_{i=1,2} i\psi_{r,i}^* (d\psi_{r,i}/dt) - H$. It is the discretized version of the GP equation called the discrete nonlinear Schorödinger equation [27] and given by

$$i \frac{\partial \psi_{r,i}}{\partial t} = -J(\psi_{r,\bar{i}} + \psi_{r-\bar{i},\bar{i}} + \psi_{r+i,\bar{i}} + \psi_{r+i-\bar{i},\bar{i}}) + \left[\left(V'_0 + \frac{2}{\gamma^2} \right) |\psi_{r,i}|^2 + \frac{1}{\gamma^2} (|\psi_{r,\bar{i}}|^2 + |\psi_{r-\bar{i},\bar{i}}|^2 + |\psi_{r+i,\bar{i}}|^2 + |\psi_{r+i-\bar{i},\bar{i}}|^2) \right] \psi_{r,i}, \quad (6)$$

where $i = 1, 2$ and $\bar{i} \equiv 2, \bar{2} \equiv 1$. The uniform stationary solution can be obtained by substituting $\psi_{r,i} = \psi_0 e^{-i\mu t}$ as $|\psi_0|^2 = (\mu + 4J)/(V'_0 + 8\gamma^{-2})$, where μ is the chemical potential. Since an important quantity to observe the dynamics of electric fluxes is the density fluctuation, we give the equilibrium density $|\psi_0|^2 = \rho_0$ by controlling the chemical potential as $\mu = \rho_0(V'_0 + 8\gamma^{-2}) - 4J$ and see the evolution of the density fluctuation $\eta = \rho - \rho_0$.

The time-dependent equation of motion for η and θ in the GH model of Eq. (2) is derived in the similar way from $L = -\sum_{r,i} \eta_{r,i} (d\theta_{r,i}/dt) - H$ as

$$\frac{d\eta_{r,i}}{dt} = 2J\rho_0 \sum_j \sin(\theta_{r,i} - \theta_{r,j}), \quad (7)$$

$$\frac{d\theta_{r,i}}{dt} = -V'_0 \eta_{r,i} - \frac{1}{\gamma^2} (\eta_{r,i} + \eta_{r-i,i} + \eta_{r,\bar{i}} + \eta_{r-\bar{i},\bar{i}}) - \frac{1}{\gamma^2} (\eta_{r+i,i} + \eta_{r,i} + \eta_{r+i,\bar{i}} + \eta_{r+i-\bar{i},\bar{i}}). \quad (8)$$

In terms of the optical lattice, the summation over j of Eq. (7) implies to take over the four atomic sites which are NN to the atomic site (r, i) ($i = 1, 2$). In terms of the gauge lattice, given an atomic link (r, i) , (r, j) takes (r, \bar{i}) , $(r - \bar{i}, \bar{i})$, $(r + i, \bar{i})$, $(r + i - \bar{i}, \bar{i})$. Equations (7) and (8) can be also derived by linearizing Eq. (6) with respect to the density $\rho_{r,i}(t) = \rho_0 + \eta_{r,i}(t)$. The constraint of the Gauss's law requires the replacement $\eta_{r,i} \rightarrow (-1)^r \eta_{r,i}$ and $\theta_{r,i} \rightarrow (-1)^r \theta_{r,i}$. We make a dimensionless form of Eqs. (6)-(8) by using the energy scale V'_0 . In solving both set of equations of motion, we use the 200×200 discretized space and the time step $\Delta t = 10^{-4}$.

As an explicit example to apply the dynamical equations, we consider the dynamical stability of a single straight flux connecting two external charges, which is prepared as an initial condition. In the confinement phase, a set flux string should be stable. To see the stability of the flux configuration, we put the density modulation $\eta_{r,1} = (-1)^r 0.1\rho_0$ for $-R \leq r_1 \leq R - 1$ in the background initial density $\psi_0 = 1$, in which the length of the flux is $R = 10$. The presence of point charges is taken into account by fixing $\eta_{R,1} = 0.1\rho_0$ and $\eta_{R-1,1} = -0.1\rho_0$ through the time evolution. The free parameters of this system are (γ^2, V'_0, J) , related to (c_1, c_2, c_3) . By using the $\Delta\tau$ -independent parameters, we expect the confinement (Higgs) phase for small (large) values of $c_1/c_2 = \gamma^2 V'_0$ and $c_3 c_2 = 2J\rho_0/V'_0$ (see Appendix A).

Figure 2(b) and (c) represent the time evolution of the density distribution η^2 calculated by the above two models. For a certain value of J , both models show similar behaviors for small values of γ^2 , where the placed density flux is stable and does not spread out. This captures the characteristics of the confinement phase with strong phase fluctuation, where the density fluctuation can be localized by the mechanism similar to the self-trapping effects as observed in a cold atom experiment [28]. However, the underlying physics is slightly different because the system in Ref.[28] possesses only on-site interaction, without long-range one. With increasing γ^2 , i.e., the Higgs coupling, the structure of the density flux is gradually lost by emitting the density waves from the charge. This emission is a characteristic of the superfluid phase, i.e., Higgs phase, where the phase-coherence can generate a long-wavelength phonon. The density waves are generated in a different way: successively in the BH model and intermittently in the GH model, propagating concentrically around the point charges with the sound

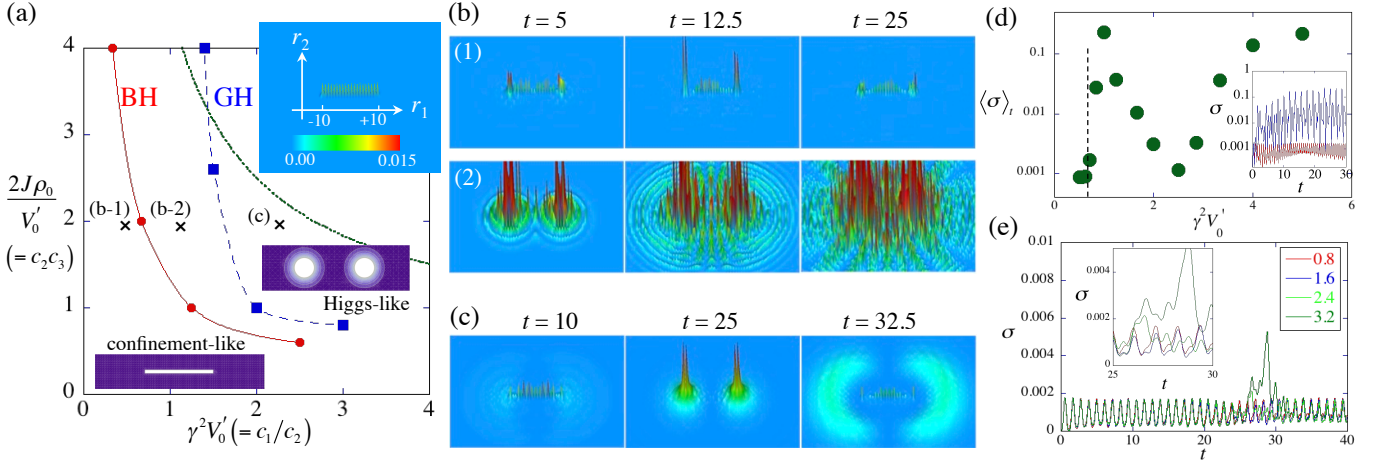

FIG. 2. Results of the dynamical simulations. (a) The dynamical phase diagram with respect to the $\Delta\tau$ -independent parameters $(\gamma^2 V'_0) - (2J\rho_0/V'_0)$ in the BH and GH models. In terms of the GH model Eq. (3), the horizontal and vertical axes correspond to c_1/c_2 and $c_3 c_2$, respectively. The two models give the different phase boundaries, where Higgs (confinement) like behavior can be observed at the right (left) of each boundary. The phase boundary of the BH model is calculated for fixed $\rho_0 = 1$. The dotted curve gives a $\mu = 0$ curve for $\rho_0 = 1$, where the amplitude dynamics of the BH model is frozen so that the overall dynamics can coincide to that of the GH model. The upper right inset shows the initial configuration of the squared density $\eta^2 = (\rho - \rho_0)^2$ in the simulation. We put the density modulation $\eta_{r,1} = (-)^r 0.1 \rho_0$ for $-R \leq r_1 \leq R-1$ with $R = 10$. (b) Time development of the density fluctuation η^2 for the BH model. The parameters are given as $(\gamma^2 V'_0, 2J\rho_0/V'_0) = (0.625, 2.0)$ (b-1, upper panels) and $(1.25, 2.0)$ (b-2, lower panels), corresponding to the confinement and Higgs regime, respectively (the parameters are also shown in (a) by crosses). The unit of time is chosen as \hbar/V'_0 , which is ~ 0.7 msec for the typical energy scale $V'_0 \sim 10$ nK. A flux keeps its initial configuration in the confinement phase (b-1), while it is disappeared by the density fluctuation in the Higgs phase (b-2). (c) The same in (b) for the GH model with the parameter $(\gamma^2 V'_0, 2J\rho_0/V'_0) = (2.4, 2.0)$ of the Higgs regime. The large amplitude density wave is generated at the point charges, being emitted intermittently. In the confinement phase, the dynamics is similar to Fig. (b-1). (d) Plot of the time average of the remnant of flux σ of Eq. (9) for the BH model. The shown results are obtained for $\rho_0 = 1$ and $2J\rho_0/V'_0 = 2$ and some values of $\gamma^2 V'_0$. The vertical dashed line gives the boundary between the confinement (left) and Higgs (right) regime. The inset shows the time evolution of $\sigma(t)$ for (b-1) (red curve) and (b-2) (blue curve). (e) Plot shows the evolution of $\sigma(t)$ for the GH model with $2J\rho_0/V'_0 = 2$ and several values of γ in the legend. The left inset is the enlarged view during $t \in [25, 30]$, where σ grows intermittently.

velocity $\sim \sqrt{J\rho_0 V'_0}$ for $\gamma^2 \gg 1$.

To judge whether the system is in confinement- or Higgs-regime by dynamical simulations, we calculate the remnants of the flux $\sigma(t)$ defined by

$$\sigma(t) = \sum_{\ell \in \text{initial flux line}} [\eta_\ell^2(t) - \eta_\ell^2(0)]^2, \quad (9)$$

where the sum is taken over the sites on which the density flux line is set initially. The flux is stable when σ is kept small during the time evolution. Figure 2 (a) shows the dynamical phase diagram obtained by the behavior of σ shown in Fig. 2(d) and (e). The rapid oscillation of σ reflects in the periodic vanish-revival cycle of the density flux. In the BH model, we calculate the time-average $\langle \sigma \rangle_t$ and determine the phase boundary by finding the point at which $\langle \sigma \rangle_t$ almost vanishes (below 0.001; see Fig. 2(d)). In the GH model, the boundary is determined by the appearance of rapid growth of $\sigma(t)$ due to the intermittent density-wave emission as seen Fig. 2(e).

It is important to note that our dynamical approach can give a new method to explore the phase structure of the LGT. The validity of our approach exactly stems from the correspondence of the LGT to the theoretical

description of the atomic systems in Sec. II. Although the dynamical results are obtained under the mean field approximation and only applicable to the GH model with the unitary gauge of the Higgs field [19], the dynamical phase boundaries of both models are qualitatively in good agreement with the result of the Monte Carlo simulations of the full GH model of Eq. (3). (see Fig. 5 and Appendix A).

The dynamical difference of the BH and GH models can be observed in the amplitude fluctuation of the simulating gauge field. Because the GH model is obtained by expanding $\rho = \rho_0 + \eta$ around the constant density $\rho_0 \gg 1$, the BH model can approximately reproduce the GH model when the Thomas-Fermi limit is satisfied; note that the boundary of the BH model in Fig. 2(a) is obtained for the particular value $\rho_0 = 1$. In addition, near the situation $\mu = 0$ represented by a dotted curve in Fig. 2(a), the density fluctuation is accidentally frozen because the development of the homogeneous wave-function is driven as $\psi_0 e^{-i\mu t}$. Then, the dynamics of the BH model is similar to the GH model. This is a reason of the decrease of $\langle \sigma \rangle_t$ around $\gamma^2 V'_0 = 2.5$. Another point is that the amplitude fluctuation in the BH model can give rise to a similar effect of the fluctuation of the

Higgs coupling. When the Higgs field moves away from the London limit, the Higgs-confinement transition may become first order and its boundary can be sharp [29]. Since our GH model corresponds to the London limit, in which the amplitude fluctuation of the Higgs field is absent, the phase boundary becomes less clear because the two phases connect with each other through crossover. The significant amplitude fluctuation in the BH model can lead to the stabilization of the Higgs phase as seen in Fig. 2(a).

IV. IMPLEMENTATION WITH COLD ATOMS

In this section we present two methods to realize V_{ab} as shown in Table I. A major way to prepare intersite interactions in BH systems is to use DDI between atoms or molecules [25, 30, 31]. In usual experiments, dipoles of an atomic cloud are uniformly polarized along a certain direction, and one may easily check that uniformly oriented dipoles generate V_{ab} different from the configuration of V_{ab} in Table I. This is partly because we consider a square lattice, and the similar requirement for V_{ab} is satisfied on the triangular or Kagome lattice [18]. Although an individual control of the polarization of a dipole at each site may achieve V_{ab} in Table I, its actual fulfillment is difficult (some discussions can be seen in the system of polar molecules [32]), and importantly the hopping process between sites with different dipole orientations are prohibited or reduced due to the conservation of the atomic spin. We note that the bipartite structures of the nanoscale ferromagnetic islands have been proposed for realizing the right Gauss law constraint using dipolar interactions [33]. Recently, there is an interesting proposal to realize V_{ab} in Table I by using the Rydberg p -states of cold atoms [34].

In Sec. IV A, we discuss the possibility to realize the values of V_{ab} in Table I by using the excited bands of an optical lattice, which is an alternative route to get intersite interactions [26]. In Sec. IV B, we discuss a system of multi-layer 2D optical lattices [35] to realize tunable DDI between of atoms. The difference from the proposal in Ref. [33] is that the long-range interaction of dipoles between *different* layers is controlled by tuning the height of the two layers and the length of dipoles in Ref.[33], while in our case, the long-range interaction in the *same* layer is controlled through the mediation of atomic interaction in *different* layers. These proposals are within reach in current experimental techniques.

A. Method A: Using excited bands of an optical lattice

The Wannier functions in excited bands have extended anisotropic orbitals compared with the lowest s -orbital band. Thus, we expect the significant intersite density-density interaction without introducing DDI between

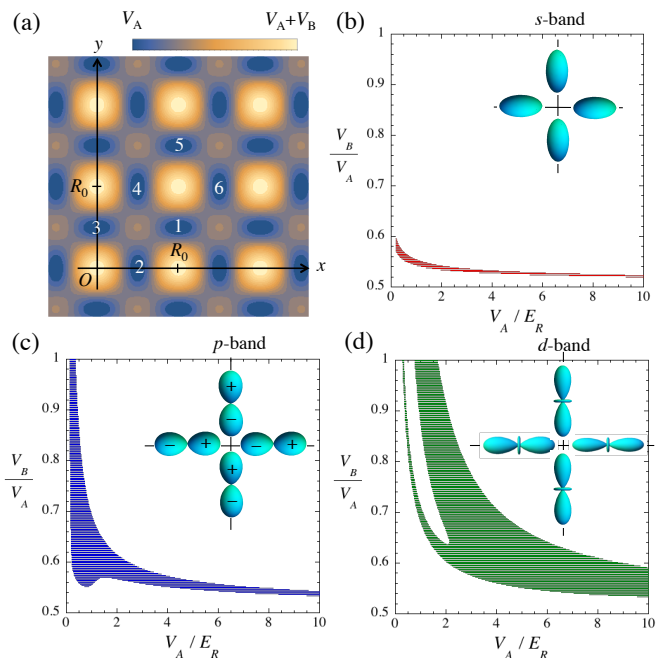

FIG. 3. Method A to realize the value of V_{ab} in Table I using excited bands of an optical lattice. (a) The profile of the optical lattice of Eq. (10) for $V_A = V_B$. The minima of the lattice are located at $(x, y) = R_0(m_x, m_y + 1/2)$ for the horizontal links and $(x, y) = R_0(m_x + 1/2, m_y)$ for the vertical links ($m_{x,y}$: integers), where $R_0 = \pi/k$ is the lattice constant. The panels (b)-(d) show the domains (colored region) that satisfy the approximated condition for the overlap integral $0.95 < O_{12}/O_{13} < 1.05$ and $O_{15}/O_{12} \leq 0.1$ in the V_A/E_R - V_B/V_A plane for s -, p -, and d -orbitals, respectively. For p - and d -orbitals, the domains bifurcate due to the radial peak structure of the Wannier function (see Appendix B).

atoms [26]. To implement this scheme, we assume the following optical lattice potential:

$$V_{OL} = V_A (\cos^2 kx + \cos^2 ky) + V_B [\cos^2 k(x-y) + \cos^2 k(x+y)], \quad V_A, V_B \geq 0, \quad (10)$$

which can be created in a current experimental setup. For $V_B/V_A > 0.5$, the potential forms a checkerboard lattice (line graph of a square lattice [24]) and its minima are characterized by anisotropic harmonic form as shown in Fig. 3(a). This anisotropy is necessary to prevent the intraband mixing dynamics. Excitation to higher orbitals can be achieved by stimulated Raman transition [36] or nonadiabatic control of the optical lattice [37, 38].

The intersite density-density interaction is proportional to the overlap integral $O_{ab} = \int d\mathbf{r} |w_a|^2 |w_b|^2$, where w_a is the Wannier function at the link (r, a) and we assume a negligibly small DDI. For the horizontal links, by approximating a minimum of the optical lattice as a quadratic form $m\omega_{ho}^2(\alpha^2 x^2 + y^2)/2$, w_a can be represented by the harmonic oscillator basis $\Phi_{\mathbf{n}}(\mathbf{r})$, where $\hbar\omega_{ho} = 2\sqrt{E_R(V_A + 2V_B)}$ with the recoil energy $E_R = \hbar^2 k^2 / 2m$

of the optical lattice and $\alpha = \sqrt{(2V_B - V_A)/(2V_B + V_A)}$. The band index takes $\mathbf{n} = (0, 0)$, $(1, 0)$, and $(2, 0)$ for the s -, p -, and d -orbitals. For the vertical links, the role of (x, y) is just exchanged by (y, x) .

The conditions in Table I read $O_{12} \approx O_{13} \gg O_{15}$. Figures 3(b)-(d) represent the parameter domain satisfying this condition with respect to V_A and V_B/V_A , where the amplitudes V_A and V_B of the optical lattice are precisely tunable parameters. Because of the characteristics of the potential Eq. (10), we can have significant overlap of the Wannier functions even for the high potential height such as $V_{A,B} = 100E_R$ for $V_B/V_A \geq 0.5$; see Appendix B for more details. For the s -orbitals the domain is limited to a narrow region ($V_B \sim 0.55V_A$) of the parameter space. Using the p - or d - orbitals allows us to get the condition of Table I more easily in the experimentally feasible condition. When the excited orbitals are used, we have significant hopping amplitudes J_{ab} not only for the NN (J) but also the 1st half of NNN (J'); the 2nd half of NNN (J'') is small because of higher potential height between the link of group (iii) as seen in Fig. 3(a).

Finally, we admit that, for actual parameter estimation, one should also try other more realistic Wannier functions such as $\sim x^c \exp(-h|x|)$ [39], although the qualitative feature captured here needs no modifications.

B. Method B: Using dipolar atoms in a multilayer optical lattice

The idea for the second method is to introduce new subsidiary 2D lattices and treat the DDI between atoms in the original 2D lattice and atoms in the subsidiary lattices by the second-order perturbation theory to obtain V_{ab} effectively. For illustrative purpose, we explicitly describe the idea by using a triple-layer system consisting of three 2D square optical lattices (layer L_A , L_B , L_C) as seen in Fig. 4(a). Here, we neglect the contribution of short-range interaction for the intersite interaction. The scheme may be reduced to a double-layer system by approaching the distance between two layers, e.g. L_A and L_B , to zero, which is discussed for realistic parameter estimation at the end of Appendix C.

The boson system on the layer L_A (we call them A-bosons) is a playground of the (2+1)D U(1) GH model, which is sandwiched by B-bosons on L_B and C-bosons on L_C . The B- and C-bosons are trapped in deep optical lattices with negligible hopping. Each layer has different basis vectors of the lattice structure as shown in Fig. 4(b) and (c). Each species of bosons is assumed to have a dipole, perpendicular to the plane of the layer. By treating the DDI between A-boson and B-boson as a perturbation, the second-order perturbation theory generates an effective intersite interaction between the A-bosons. So is the DDI between A- and C-bosons, which generates another intersite interactions between the A-bosons. These two kinds of interactions may be tuned to realize V_{ab} as given in Table I. We omit the DDI between the B-

FIG. 4. (a) The structure of a triple-layer 2D optical lattice. The LGT is simulated on the lattice of black solid lines. The layers are separated by distance ℓ_{AB} and ℓ_{AC} . The panels (b) and (c) show the projective mapping of L_A (red lines) and L_B (blue lines), and L_A and L_C (orange lines), respectively. The panel (d) shows the unit cell of the projective mapping of the all layers. The site label of L_A and L_C are denoted as k and l , respectively. For the layers L_B and L_A , we take the NN DDI between atoms on the sites k in L_B and $k \pm \delta_x(\delta_y)$ in L_A into account. For L_C and L_A , we take the NN DDI between atoms on the sites l in L_C and $l + \delta_+(\delta_-)$ in L_A into account.

and C-bosons because of the large separation.

Let us focus on Fig. 4(d). When one projects the sites of L_B onto L_A , their image locates on the center of each plaquette of the L_A lattice. Similarly, the image of sites of L_C locates on the middle of NN pairs of the L_A sites. In L_A , the A-bosons at different sites have the repulsive DDI. Furthermore, the A- and B(C)-bosons are coupled through the NN attractive DDI given by

$$\begin{aligned} H_{AB} &= V_{AB} \sum_{k,\delta} \rho_{A,k+\delta} n_{B,k}, \\ H_{AC} &= V_{AC} \sum_{l,\tilde{\delta}} \rho_{A,l+\tilde{\delta}} n_{C,l}, \end{aligned} \quad (11)$$

where $\rho_{A,k}$ and $n_{B(C),k}$ are boson densities at the site k and $V_{AB(C)} < 0$ is the DDI, which is tunable by controlling the interlayer separation. Our strategy is to trace out B- and C-bosons to get the effective attractive intersite interactions between the A-bosons themselves. According to the usual second-order perturbation theory with $H_{AB(C)}$ as perturbation, the effective attractive interaction between A-bosons may be estimated as $\sim -V_{AB}^2 \sum_{k,\delta,\delta'} \rho_{A,k+\delta} \rho_{A,k+\delta'}$ and $-V_{AC}^2 \sum_{l,\tilde{\delta}} \rho_{A,l+\tilde{\delta}} \rho_{A,l-\tilde{\delta}}$. They are due to density fluctuations of B- and C-bosons, respectively. The former term contributes a constant to

V_{ab} for (a,b) of the groups (i,iii) of Table I, while the latter contributes a constant only for the group (i). Then one may fulfill the condition of V_{ab} in Table I. The detailed calculation of the effective interaction and the experimental feasibility are described in Appendix C. Although there is a small contribution of long-range interaction beyond the NNN links due to the power-law tail of r^3 , this correction may suppress the density fluctuation and result in the enhancement of the confinement phase.

V. CONCLUSION AND OUTLOOK

In conclusion, realization of the quantum simulator of the U(1) lattice-gauge Higgs model provides a significant innovation to tackle unresolved problems such as inflation universe, being possible to be constructed by the cold-atomic architecture. The phase structure of the atomic simulators may be explored by the non-equilibrium dynamics, where the electric flux dynamics can be observed from the behavior of the density fluctuation. We proposed two experimentally feasible schemes (Method A and B) to respect the constraint of Gauss's law and locality of the gauge interaction in the atomic simulators.

Many works have been devoted to the dynamical properties of phase defects, namely quantized vortices, by analyzing the GP equation [40]. In terms of the gauge theory, these phase defects correspond to the magnetic fluxes. Our work focuses on the density fluxes, corresponding to electric fluxes, whose dynamics are under constraint by the Gauss's law. Such a density flux in the GP model has not been discussed before and this point of view could open the door for new avenue of the GP dynamics, such as dynamical features of various configurations of an electric flux or many fluxes. These non-equilibrium dynamics are interesting themselves, although they could also give references as a guide not only to the atomic simulator experiments but also to the LGT. The dynamical equations can be derived and give some insights for various models of the LGT.

The other problems for the future study includes the clarification of the global phase diagram of Eq. (3) for the general sets of parameters and of how to implement the general terms in Eq. (3) experimentally. It has been proposed in Ref. [19] that the Higgs coupling (c_{1i} -term) in the spatial dimension can be implemented by using an idea of Ref. [41]. An idea to generate the spatial plaquette (c_{2ij} -term) is discussed in Ref. [42]. There is still insufficient discussion on how to combine these schemes toward the quantum simulation of the full GH model, which is a subject for future study. Fine tuning of the intersite density-density interaction is also an important task, and we believe that the method in Sec. IV A is the most feasible scheme in actual experiments. Our method in Sec. IV B provides a new scheme for tuning the intersite atom-atom interactions, and more elaborated discussion using concrete atomic species, optical lattice structures, etc., remains to be studied. All of these issues will

be reported in future publications.

Appendix A: Phase structure of the U(1) GH model

Let us explain the phase structure of the gauge-Higgs model defined by Eq. (3) with asymmetric couplings $c_{1\mu}, c_{2\mu\nu}$ given by Eq. (4). First, we note that the (2+1)D version of the standard 4D U(1) Higgs gauge theory [20], which is considered in HEP and has the symmetric couplings ($c_{1\mu} = c_1 \geq 0, c_{2\mu\nu} = c_2 \geq 0, c_{3,4,5} = 0$ in Eq. (3)), is always in the confinement phase [43], in which the phase $\theta_{x,\mu}$ is unstable by strong fluctuation. In our model, inclusion of sufficient c_3 in addition to the asymmetric couplings $c_{1\mu}$ and $c_{2\mu\nu}$ lets the system enter into the ‘‘Higgs’’ phase, where both $\theta_{x,\mu}$ and φ_x are stable [see Fig. 5].

To identify the location of the transitions, we measure the internal energy $U = \langle A \rangle$ and the specific heat $C = \langle A^2 \rangle - \langle A \rangle^2$ by using the standard Metropolis algorithm in Monte Carlo (MC) simulation with the periodic boundary condition for the cubic lattice of size $V = L^3$ with L up to 40. The typical number of sweeps is $100000 + 10000 \times 10$, where the first number is for thermalization and the second one is for measurement. The errors of U and C are estimated by the standard deviation over 10 samples. Acceptance ratios in updating variables are controlled to be $0.6 \sim 0.8$.

Explicitly, we confine ourselves to the case $c_4 = c_5 = 0$ and obtain the phase diagram in the $c_1 - c_3$ plane for several values of c_2 . The result is presented in Fig. 5. There are two phases: the Higgs phase in the large c_3 region (upper region) and the confinement phase in the small c_3 region (lower region). The confinement-Higgs transition here should correspond to various phase transitions such as the superconducting transition, the mass generation in the standard model, and the believed one to take place in the early universe [22, 23]. In contrast to the phase diagram of the (3+1)D model for $c_4 = c_5 = 0, c_1 = c_3$, and $c_2 \geq 0$ [19], the Coulomb phase is missing due to the low dimensionality.

To understand Fig. 5, let us consider some limiting cases. First, after choosing the unitary gauge $\phi_x = 1$, let us consider the limit $c_1 \rightarrow \infty$. Then the c_1 term makes

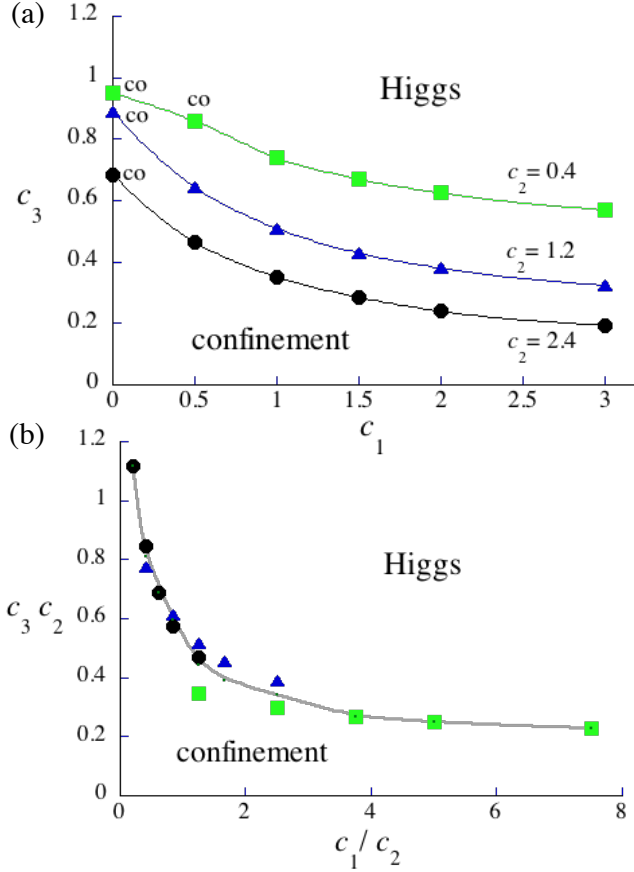

FIG. 5. Phase diagram of the (2+1)D U(1) lattice GH model of Eq. (3) with asymmetric couplings $c_{1\mu}$ and $c_{2\mu\nu}$ given by Eq. (4) and $c_4 = c_5 = 0$. (a) Three curves connect transition points in the c_1 - c_3 plane for $c_2 = 0.4, 1.2, 2.4$ from above, which separate the Higgs phase (above) and the confinement phase (below). The transition points are located at the peak of C as a function of c_3 for fixed c_1 . They are (i) second-order (no marks) where the peak of C develops as the size L increases and U exhibits no hysteresis or (ii) cross-over or Kosterlitz-Thouless transition (both marked with co) where the peak does not develop. (b) The transition points on (a) are arranged in the (c_1/c_2) - $(c_3 \cdot c_2)$ plane ($\gamma^2 V'_0 - 2J\rho_0/V'_0$ plane). They almost sit on a single curve (gray line) (See the comment right after Eq. (5)).

$\theta_{x,0} = 0 \pmod{2\pi}$, and the action becomes

$$A_{c_1=\infty} = c_2 \sum_x \sum_{i=1}^2 \cos(\theta_{x+0,i} - \theta_{x,i}) + c_3 \sum_x \left[\cos(\theta_{x,1} - \theta_{x,2}) + \cos(\theta_{x,1} + \theta_{x+1,2}) + \cos(\theta_{x+1,2} - \theta_{x+2,1}) + \cos(\theta_{x,2} + \theta_{x+2,1}) \right], \quad (\text{A1})$$

up to constant. This is viewed as a 3D XY spin model with asymmetric couplings, where $\theta_{x,i}$ ($i = 1, 2$) on the link $(x, x+i)$ is the XY spin angle $\tilde{\theta}_{\tilde{x}}$. In fact, the c_3 term is their NN coupling in the 12 plane and the c_2 term is their NN coupling along the $\mu = 0$ axis. The

region of sufficiently large c_2 and c_3 is the ordered phase of this XY spins, and corresponds to the Higgs phase with small gauge-field $(\theta_{x,\mu})$ fluctuations. As a check of Fig. 5, let us consider the case $c_2 = c_3$ of Eq. (A1), which reduces to the symmetric 3D XY spin model of $A_{3\text{DXY}} = c_{\text{XY}} \sum_{\tilde{x}, \mu} \cos(\tilde{\theta}_{\tilde{x}+\mu} - \tilde{\theta}_{\tilde{x}})$. It is known to have a genuine second-order phase transition at $c_{\text{XY}} \simeq 0.45$. Therefore the transition line in Fig. 5 (b) should approach to $c_2 \cdot c_3 \rightarrow 0.45^2 \simeq 0.20$ as $c_1/c_2 \rightarrow \infty$ as it shows.

Next, let us consider the case $c_2 = 0$. Then, each variable $\theta_{x,0}$ appears only through the c_1 term without couplings to other variables (we take the unitary gauge as before). Then the dynamics is controlled by the c_3 term. Again, this term is viewed as the energy of the XY spins θ_{xi} ($i = 1, 2$). However they have no coupling along the $\mu = 0$ direction, and therefore the system is a collection of decoupled 2D XY spin models. 2D XY spin model is known to exhibit Kosterlitz-Thouless (KT) transition which is infinitely continuous. Thus, although it is not drawn in Fig. 5, there should be added a horizontal line (independent of c_1) for $c_2 = 0$ consisting of a collections of KT transitions at around $c_3 \sim 0.96$. We understand that the crossover points appearing in the smaller c_1 part in each curve for three c_2 drawn in Fig. 5 are the remnants of these KT transitions. They have a chance to be a genuine KT transition, although we called them crossover here. Another support of this interpretation is to consider the case $c_1 = 0$. Then there is no source term for $\theta_{x,0}$ and $\theta_{x,0}$ should determine their dynamics only through the c_2 term. Thus, even $\theta_{x,i}$ could be set constant with no fluctuations, $\theta_{x,0}$ has the NN coupling in each 12 plane. However, two dimensions is not enough to stabilize $\theta_{x,0}$. In turn, the c_2 term is not enough to sustain the coupling between $\theta_{x,i}$ along the $\mu = 0$ direction. The dynamics of $\theta_{x,i}$ is essentially from the c_3 term, which is the 2D XY model as explained. Therefore, the transition, if any, for $c_1 = 0$ may be a KT transition. No genuine second-order one is possible.

The last case is $c_2 = \infty$. Then $\theta_{x,\mu}$ is frozen to be a pure gauge configuration, $\theta_{x,\mu} = \lambda_{x+\mu} - \lambda_x$. By plugging this into the c_1 and c_3 term, we obtain

$$A_{c_2=\infty} = c_1 \sum_x \cos(\lambda_{x+3} - \lambda_x) + 2c_3 \sum_x \left[\cos(\lambda_{x+1} - \lambda_{x+2}) + \cos(\lambda_x - \lambda_{x+1+2}) \right], \quad (\text{A2})$$

which belongs again to the class of 3D XY spin models, where λ_x is the XY spin angles on the site x . So we should have a second-order transition at $c_2 = \infty$ as long as both c_1 and c_3 are nonvanishing. This is consistent with Fig. 5.

Let us finally comment on the transition line of Fig. 5(b) and the boundaries of Fig. 2(a) calculated by dynamical simulation in Sec. III. Their behaviors in the (c_1/c_2) - $(c_3 \cdot c_2)$ plane are qualitatively consistent but different in quantitative comparison. We understand that there are no inconsistency in these results because the two methods, MC and GP, are different in nature: MC

is static and GP is dynamical, they treat fluctuations in contrasting manners, and especially, the dynamical simulations necessarily exhibit various properties of the system according to their setup and probes, etc. This certainly motivates exact quantum and dynamical simulation of the BH model in experiments.

Appendix B: Calculation of overlap integrals

In this section, we describe the calculation of the overlap integrals discussed in Sec. III A. For the horizontal links of the potential V_{OL} of Eq. (10), the minimum is approximated by the harmonic oscillator $V_{hx} = m\omega_{ho}^2(\alpha^2 x^2 + y^2)/2$. The basis function of V_{hx} is given by

$$\Phi_{\mathbf{n}}(\sqrt{\alpha}x, y) = A_{\mathbf{n}} H_{n_x} \left(\sqrt{\alpha} \frac{x}{a_{ho}} \right) H_{n_y} \left(\frac{y}{a_{ho}} \right) e^{-(\alpha x^2 + y^2)/2a_{ho}^2}, \quad (B1)$$

where H_n is the Hermite polynomial, $A_{\mathbf{n}}$ the normalization factor, and $a_{ho} = \sqrt{\hbar/m\omega_{ho}}$ the harmonic oscillator length

The s , p , and d orbitals for these links correspond to $\mathbf{n} = (n_x, n_y) = (0, 0)$, $(1, 0)$, and $(2, 0)$. As the Wannier function $w_a(\mathbf{r})$ at the link (r, a) , we use $\Phi_{\mathbf{n}}$ with (x, y) measured from the center of the link. For the vertical links, the minimum is also approximated as $V_{hy} = m\omega_{ho}^2(x^2 + \alpha^2 y^2)/2$ and the basis function is $\Phi_{\mathbf{n}}(x, \sqrt{\alpha}y) = A_{\mathbf{n}} H_{n_x}(x/a_{ho}) H_{n_y}(\sqrt{\alpha}y/a_{ho}) e^{-(x^2 + \alpha y^2)/2a_{ho}^2}$. The s , p , and d orbitals for these links correspond to $\mathbf{n} = (n_x, n_y) = (0, 0)$, $(0, 1)$, and $(0, 2)$. Then, the Wannier functions $w_a(\mathbf{r})$, relevant to the following calculations, are given as follows;

$$\begin{aligned} w_1(\mathbf{r}) &= \Phi_{\mathbf{n}}(\sqrt{\alpha}R_0(\tilde{x} - 1/2), R_0\tilde{y}), \\ w_2(\mathbf{r}) &= \Phi_{\mathbf{n}}(R_0\tilde{x}, \sqrt{\alpha}R_0(\tilde{y} + 1/2)), \\ w_3(\mathbf{r}) &= \Phi_{\mathbf{n}}(\sqrt{\alpha}R_0(\tilde{x} + 1/2), R_0\tilde{y}), \\ w_5(\mathbf{r}) &= \Phi_{\mathbf{n}}(\sqrt{\alpha}R_0(\tilde{x} - 1/2), R_0(\tilde{y} - 1)), \end{aligned} \quad (B2)$$

where R_0 represents the lattice spacing and we shift the origin of the coordinate to $(R_0/2, R_0/2)$ of Fig. 3(a). The length scale of the coordinate is normalized by R_0 and the dimensionless coordinates are denoted by putting tildes.

The intersite interaction strength V_{ab} is proportional to the overlap integrals $O_{ab} = \int d\mathbf{r} |w_a|^2 |w_b|^2$. It is sufficient to calculate only the integrals for the link pairs $(a, b) = (1, 2)$, $(1, 3)$, and $(1, 5)$, because $O_{12} = O_{23} = O_{34} = O_{41}$, $O_{13} = O_{24}$, and $O_{15} = O_{26}$ due to the lattice symmetry.

The typical results of the overlap integrals for the three orbitals are shown in Fig. 6 for $V_B/V_A = 0.6$ as a function of V_A . We also show the integral for on-site contribution $O_{11} = \int d\mathbf{r} |w_a|^4$ and the hopping integrals $J = \int d\mathbf{r} w_1(-\hbar^2 \nabla^2/2m + V_{OL})w_2$, $J' = \int d\mathbf{r} w_1(-\hbar^2 \nabla^2/2m + V_{OL})w_3$, and $J'' = \int d\mathbf{r} w_1(-\hbar^2 \nabla^2/2m + V_{OL})w_5$. In any case, O_{11} is monotonically increased with V_A , and J'' and

FIG. 6. Overlap integral O_{ab} and hopping integrals J , J' , and J'' as a function of V_A/E_R for $V_B/V_A = 0.6$. The panels (a), (b), and (c) corresponds to the cases of s -, p -, and d -wave orbitals. Using O_{ab} , the density-density is written by $V_{ab}/E_R = (8a/\pi l_z)O_{ab}$ with the s -wave scattering length a and the typical length scale l_z along the z -direction. The hopping is also normalized by E_R and its negative value is plotted by the absolute value. In the p -orbital case, $J_{12}(=J)$ and $J_{13}(=J')$ become negative, but there is no frustration because of $J_{23}, J_{41} > 0$ and $J_{34}, J_{24} < 0$.

O_{15} (not seen in Fig. 6) are negligibly small. In the case of the s -orbital, O_{12} and O_{13} are also monotonically decreasing functions, so that the range satisfying $O_{12} \approx O_{13}$ is only limited by a narrow range or a point with respect to V_A . On the other hand, for the p - and d -orbitals O_{12} and O_{13} changes non-monotonically because of the node structure and the extended amplitude profile of the wave

functions. This fact extends the range of $O_{12} \approx O_{13}$ as seen in Fig. 6(b) and (c).

Note that the hopping integrals J and J' are of $\mathcal{O}(1)$ even for $V_A = 100E_R$. This is because the energy barrier between links of group (i) and (ii) in Table I is the sub-maximum with the height $2V_B - V_A$ at $(R_0/2, R_0/2)$ in Fig. 3(a). Since, the value of $J(J')$ is bigger than that of $O_{12(13)}$ by two orders of magnitude, one needs to increase considerably the s -wave scattering length via a Feshbach resonance to get the exact Gauss's law constraint, namely, $V_{ab} \gg J$.

Appendix C: Effective intersite interaction in the triple-layer system of Sec. IV B

In this section, we apply the second-order perturbation theory to the triple-layer system in Sec. IV B to derive the effective intersite interaction of A-bosons, and estimate the possible values of involved parameters to realize V_{ab} of Table I. After that, we briefly explain a double-layer system in which magnitude of the intersite interaction of A-bosons is controlled in a similar way.

We first confine ourselves to the subsystem of the A- and B-bosons (two layers L_A and L_B) which has the NN DDI, H_{AB} of Eq. (11). It implies that the B-boson on the site k interacts with the four NN A-bosons on the sites $k \pm \delta_{x(y)}$ as seen in Fig. 4(d). V_{AB} in H_{AB} is expressed as

$$V_{AB} = \int d\mathbf{r} d\mathbf{r}' U_{DD}(\mathbf{r}, \mathbf{r}') |w_A(\mathbf{r})|^2 |w_B(\mathbf{r}')|^2, \\ U_{DD}(\mathbf{r}, \mathbf{r}') = \frac{C}{4\pi|\mathbf{r} - \mathbf{r}'|^3} \left(1 - \frac{3\ell_{AB}^2}{|\mathbf{r} - \mathbf{r}'|^2} \right), \quad (C1)$$

where $\mathbf{r}(\mathbf{r}')$ is the position of A(B)-boson, $w_{A(B)}(\mathbf{r})$ is their Wannier function, and $C = \mu_0 \tilde{\mu}_A \tilde{\mu}_B$; μ_0 is the magnetic permeability of the vacuum and $\tilde{\mu}_{A(B)}$ is the magnetic moment of A(B)-atoms.

We assume that the B-bosons of L_B have a chemical potential $\mu_B (> 0)$, a negligibly small NN hopping amplitude due to a deep trapping potential, an on-site repulsion $U_B (> 0)$, and the NN DDI with A-bosons V_{AB} . One may forget the DDI between B-bosons, because it is a constant due to negligible NN hopping. Then, the Hamiltonian \hat{H}_B and the partition function $Z_B = \text{Tr} \exp(-\beta \hat{H}_B)$ for the subsystem of B-bosons are written by using the B-boson density operator \hat{n}_k at the site k as

$$\hat{H}_B = \sum_k \left[-\mu_B \hat{n}_k + U_B \hat{n}_k (\hat{n}_k - 1) + V_{AB} \sum_{\delta=\pm\delta_{x,y}} \hat{n}_k \hat{\rho}_{k+\delta} \right], \\ Z_B = \prod_k z_{B,k}, \quad z_{B,k} = \sum_{n=0}^{\infty} \exp \left[-\beta (E_n + n V_{AB} \sum_{\delta} \hat{\rho}_{k+\delta}) \right], \\ E_n = -\mu_B n + U_B n(n-1). \quad (C2)$$

By assuming $\mu_B, U_B \gg V_{AB}$, we expand $z_{B,k}$ up to

$\mathcal{O}(V_{AB}^2)$,

$$z_{B,k} = \sum_{n=0}^{\infty} e^{-\beta E_n} \left[1 - n W_k + \frac{1}{2} n^2 (W_k)^2 \dots \right] \\ = F_0 \left[1 - \frac{F_1}{F_0} W_k + \frac{1}{2} \frac{F_2}{F_0} (W_k)^2 \dots \right], \\ W_k = \beta V_{AB} \sum_{\delta} \hat{\rho}_{k+\delta}, \quad F_m \equiv \sum_{n=0}^{\infty} n^m e^{-\beta E_n}. \quad (C3)$$

Then we have

$$Z_B = (F_0)^{L^2} \exp \left\{ \sum_k \left[\langle -n \rangle_0 W_k + \frac{1}{2} (\Delta n)^2 (W_k)^2 + \dots \right] \right\}, \\ \langle n^m \rangle_0 \equiv \frac{F_m}{F_0}, \quad (\Delta n)^2 \equiv \langle n^2 \rangle_0 - \langle n \rangle_0^2. \quad (C4)$$

The first-order terms $\propto W_k$ are renormalized to the chemical potential of A-bosons and the second-order terms define the effective density-density interaction Hamiltonian \hat{H}_{ABA} of A-bosons induced by B-boson density fluctuation $(\Delta n)^2$,

$$\hat{H}_{ABA} = -\frac{\beta}{2} (\Delta n)^2 V_{AB}^2 \sum_k \sum_{\delta, \delta'} \hat{\rho}_{k, \delta} \hat{\rho}_{k, \delta'}. \quad (C5)$$

The DDI between A-atoms and C-atoms can be analyzed in the same way, and we obtain another effective density-density interaction for the A-bosons, $\hat{H}_{ACA} = -(\beta/2) (\Delta n')^2 V_{AC}^2 \sum_{l, \bar{\delta}, \bar{\delta}'} \hat{\rho}_{l+\bar{\delta}} \hat{\rho}_{l+\bar{\delta}'}$, where $(\Delta n')^2$ is obtained by replacing μ_B, U_B by μ_C, U_C in $(\Delta n)^2$.

The sum $\hat{H}_{ABA} + \hat{H}_{ACA}$ contributes to the coefficients V_{ab} of the intersite density-density interactions for A-bosons as follows;

$$\text{For NN links (group (i) in Table I),} \\ V_{ab} = V - \beta (\Delta n)^2 V_{AB}^2 - \beta (\Delta n')^2 V_{AC}^2,$$

For NNN links,

$$V_{ab} = \begin{cases} V' & \text{for group (ii)} \\ V' - \beta (\Delta n)^2 V_{AB}^2 & \text{for group (iii)}, \end{cases} \quad (C6)$$

where V and V' are the direct DDI for NN and NNN link pairs, respectively. The condition for V_{ab} in Table I can be established by adjusting two inter-layer distances ℓ_{AB} and ℓ_{AC} and density fluctuations $(\Delta n)^2(\mu_B, V_B, \beta)$ and $(\Delta n')^2(\mu_C, V_C, \beta)$ as

$$\beta (\Delta n')^2 V_{AC}^2 = V - 2V', \\ \beta (\Delta n)^2 V_{AB}^2 = V' (= \gamma^{-2}). \quad (C7)$$

Let us present some brief account for an example and estimation of the experimental parameters that satisfy the tuning relations Eq.(C7). We shall report detailed discussion on this example and related topics in a future publication.

For bosons loaded in each layer we consider ^{52}Cr atoms [44] as A bosons, ^{87}Rb atoms as B bosons, and ^{168}Er

FIG. 7. Making a double-layer system with three kinds of dipole atoms, A, B and C. (i) We prepare a 3D optical lattice. Each $x-y$ plane is separated by the distance ℓ_z and has the 2D lattice structure of the superposition of the three layers $L_{A,B,C}$ shown in Fig. 3. Then we supply the A,B,C atoms so that every $x-y$ layer is viewed as the triple-layer system of Fig. 3 with $\ell_{AB} = \ell_{AC} = 0$. (ii) We blow almost all the atoms off in such a way that only the A and B atoms in one $x-y$ layer and the C atoms in the next layer left. The resulting double-layer system is viewed as the triple-layer system of Fig. 3 with $\ell_{AB} = 0$ and $\ell_{AC} = \ell_z$.

atoms [45] as C bosons. They have the permanent magnetic moments $6\mu_{BM}$, μ_{BM} , and $7\mu_{BM}$ (μ_{BM} is a Bohr magneton), respectively. Then we are interested in the effective double-layer system, which is obtained from the triple-layer system explained above by choosing $\ell_{AB} = 0$. The reason for using the double-layer system is to make the intersite interaction as large as possible because the magnetic moment of ^{87}Rb atom is small.

The method to make such a double-layer system is sketched in Fig. 7. First, one prepares the 3D layer

system as shown in Fig. 7(i) by emitting three standing waves with the wavelengths satisfying $2\lambda_1 = \sqrt{2}\lambda_2 = \lambda_3$ (e.g., $\lambda_1 = 410\text{nm}$, $\lambda_2 = 580\text{nm}$ and $\lambda_3 = 820\text{nm}$) in eight appropriate directions in the $x-y$ plane, each being separated by 45 degrees. In addition, we emit another standing-wave laser in the z -direction with the wavelength λ_z to establish the 3D structure. Because ^{52}Cr , ^{87}Rb and ^{168}Er exhibit the specific strong absorptions of photon with wave length 425nm, 780nm and 401nm, respectively, above standing waves load these atoms to the sites of corresponding layer $L_{A,B,C}$ [46]. This completes the step (i) in Fig. 7.

In the second step (ii) on Fig. 7, one needs to remove almost all the atoms except for those in two adjacent $x-y$ layers. This can be experimentally realized by using the technique of a position-dependent microwave transfer in a magnetic field gradient perpendicular to the layers [47] successively. This achieve to make an effective double-layer system with $\ell_{AB} = 0$, $\ell_{AC} = \ell_z$.

Finally, let us estimate the parameters to satisfy the tuning relation Eq. (C7). By making a straightforward calculation using DDI, we find that the following is a typical example of parameters :

$$\begin{aligned} V &\sim \frac{36\mu_0\mu_{BM}^2}{4\pi\lambda_2^3}, \quad \ell_{AC} = \ell_z \sim 580 \text{ [nm]}, \\ \beta &\sim \frac{1}{2V}, \quad U_B \sim 0.3V, \quad \mu_B \sim 2.5V, \\ U_C &\sim 1.3V, \quad \mu_C \sim 2V. \end{aligned} \quad (\text{C8})$$

The average densities per site are ~ 560 for B bosons and ~ 8 for C bosons. The ratio $|V_{AB(C)}/\mu_{B(C)}|$ is ~ 0.192 (~ 0.585), which seems to validate the perturbation theory.
